

## RESEARCH LETTER

10.1002/2016GL068710

## Key Points:

- The Mississippi River is an important N<sub>2</sub>O source throughout the ice-free period
- The N<sub>2</sub>O:NO<sub>3</sub><sup>-</sup> mass ratio is nonlinear, implying an upper bound on N<sub>2</sub>O concentrations
- A doubling of riverine NO<sub>3</sub><sup>-</sup> would increase N<sub>2</sub>O emissions by about 40%

**Abstract** The U.S. Corn Belt is one of the most intensive agricultural regions of the world and is drained by the Upper Mississippi River (UMR), which forms one of the largest drainage basins in the U.S. While the effects of agricultural nitrate (NO<sub>3</sub><sup>-</sup>) on water quality in the UMR have been well documented, its impact on the production of nitrous oxide (N<sub>2</sub>O) has not been reported. Using a novel equilibration technique, we present the largest data set of freshwater dissolved N<sub>2</sub>O concentrations (0.7 to 6 times saturation) and examine the controls on its variability over a 350 km reach of the UMR. Driven by a supersaturated water column, the UMR was an important atmospheric N<sub>2</sub>O source (+68 mg N<sub>2</sub>O N m<sup>-2</sup> yr<sup>-1</sup>) that varies nonlinearly with the NO<sub>3</sub><sup>-</sup> concentration. Our analyses indicated that a projected doubling of the NO<sub>3</sub><sup>-</sup> concentration by 2050 would cause dissolved N<sub>2</sub>O concentrations and emissions to increase by about 40%.

## 1. Introduction

The Upper Mississippi River (UMR) drains nearly 492,000 km<sup>2</sup> of the U.S. Corn Belt [*Natural Resources Conservation Service*, 2012], one of the most intensively cultivated regions on the planet. Within the UMR basin, more than half of the U.S. share of nitrogen (N) fertilizers are applied [*Griffis et al.*, 2013; *Food and Agriculture Organization*, 2015] to produce 40% of the nation's corn [*NRCS*, 2012]. These activities have amplified river N loading, mainly as nitrate (NO<sub>3</sub><sup>-</sup>) [*Turner and Rabalais*, 1991; *Panno et al.*, 2006]. Much effort has focused on the effects of excessive N on water quality [*Rabalais*, 2002] and the ability of the UMR to reduce downstream transport [*Richardson et al.*, 2004; *Strauss et al.*, 2004, 2011] to estuary systems. However, measurements of nitrous oxide (N<sub>2</sub>O), the dominant stratospheric ozone-depleting substance [*Ravishankara et al.*, 2009] and an important greenhouse gas [*Hartmann et al.*, 2013], in the UMR are conspicuously absent in the literature, representing a significant knowledge gap in our understanding of the regional controls on dissolved N<sub>2</sub>O concentrations and emissions in heavily modified agricultural rivers.

Rivers are globally significant sources of N<sub>2</sub>O to the atmosphere [*Beaulieu et al.*, 2011; *Turner et al.*, 2015], responsible for 10%–17% of the anthropogenic budget [*Beaulieu et al.*, 2011; *Syakila and Kroeze*, 2011]. Yet rivers remain one of the most uncertain N<sub>2</sub>O sources [*Nevison*, 2000], largely due to low spatiotemporal sampling resolution that is unable to resolve the high variability of surface water N<sub>2</sub>O concentrations caused by dynamic production and consumption processes. Nitrous oxide production via denitrification and nitrification in the water column [*Beaulieu et al.*, 2010] and sediments [*Boyer et al.*, 2006; *Marzadri et al.*, 2014] causes rivers to become saturated with N<sub>2</sub>O that is emitted to the atmosphere. Generally, the degree of N<sub>2</sub>O saturation increases with the concentration of NO<sub>3</sub><sup>-</sup> and ammonium (NH<sub>4</sub><sup>+</sup>), indicating that emissions from large rivers are derived from in situ N<sub>2</sub>O production [*Beaulieu et al.*, 2010] rather than terrestrial delivery. Global model simulations suggest a doubling of N loading in rivers by the year 2050 [*Seitzinger et al.*, 2002], implying that N<sub>2</sub>O emissions from rivers, including the UMR, will likely increase. However, the relationship between dissolved N<sub>2</sub>O concentrations in rivers and N loading is poorly constrained because obtaining these types of data is logistically challenging and, consequently, observations are very limited.

Recent studies indicate that surface water N<sub>2</sub>O concentrations behave nonlinearly, plateauing in response to a number of environmental drivers, including dissolved oxygen concentration [*Rosamond et al.*, 2012] and

water temperature [Venkiteswaran *et al.*, 2014]. Observations that  $\text{N}_2\text{O}$  concentrations increase at a decreasing rate are likely caused by the inverse relation between N loading and removal efficiency [Mulholland *et al.*, 2008]. This nonlinearity implies that  $\text{N}_2\text{O}$  emissions will not increase proportionally with N loading projections, especially as a river becomes N saturated. Characterizing the  $\text{N}_2\text{O}:\text{NO}_3^-$  mass ratio should provide an upper constraint on  $\text{N}_2\text{O}$  concentrations in N-rich systems and provide insights regarding how these rivers may respond under business-as-usual N scenarios.

Here we present the largest freshwater dissolved  $\text{N}_2\text{O}$  concentration data set to date and the first  $\text{N}_2\text{O}$  surface water concentration measurements from the UMR to (1) explore the biochemical factors that control the degree of riverine  $\text{N}_2\text{O}$  saturation, (2) identify  $\text{N}_2\text{O}$  hot spots, and (3) predict how  $\text{N}_2\text{O}$  concentrations will respond to future N loading.

## 2. Materials and Methods

### 2.1. Site Description

For this study, we considered a portion of the UMR that extends from Minneapolis, MN, through Pool 8 (near La Crosse, WI). Along this stretch, eight lock and dam combinations have been installed to facilitate navigation. The river is organized into pools to describe river sections between two neighboring dams. In addition to the main channel, a pool includes impounded waters, side channels, and backwaters [Strauss *et al.*, 2011]. The temporal (10 April, 16 June, 4 August, and 13 October) and spatial dynamics of  $\text{N}_2\text{O}$  concentration were observed in Pool 8, a  $104 \text{ km}^2$  section of the UMR upstream of Lock and Dam 8. From 1 to 3 August 2015, a 350 km reach from Minneapolis, Minnesota, to Pool 8 provided a regional-scale assessment of  $\text{N}_2\text{O}$  concentration patterns in the UMR.

### 2.2. Water Sampling

We used a boat-mounted flow-through sampling system [Crawford *et al.*, 2015] to continually measure surface water  $\text{N}_2\text{O}$  and other limnological parameters. In brief, we pumped surface water (0.3 m) to a series of sensors and stripped the dissolved gases using a sprayer-type equilibration device [Crawford *et al.*, 2015]. This type of equilibrator has a fast response time [Santos *et al.*, 2012; Yoon *et al.*, 2016] and has been used in oceanic  $\text{N}_2\text{O}$  campaigns [Bange *et al.*, 1996; Arévalo-Martínez *et al.*, 2013, 2015; O'Reilly *et al.*, 2015] but has never been used to measure  $\text{N}_2\text{O}$  in freshwater systems. Equilibrator headspace air was drawn through a desiccant tube before entering a Teledyne gas filter correlation  $\text{N}_2\text{O}$  analyzer (Model M320EU2; Teledyne Instruments, City of Industry, CA, USA) [Fassbinder *et al.*, 2013; Turner *et al.*, 2015]. A circular loop was created by returning sample air back to the equilibrator device. A data logger (Model 23X; Campbell Scientific, Logan, UT, USA) recorded the  $\text{N}_2\text{O}$  analyzer output at 1 Hz for postprocessing.

This system, the Fast Limnology Automated Measurement (FLAMe) platform, has been used extensively to monitor dissolved  $\text{CO}_2$  and  $\text{CH}_4$  on the Mississippi River [Crawford *et al.*, 2016]. The FLAMe instrument panel consisted of a YSI sonde (Model EXO2; Yellow Springs, OH, USA), an optical  $\text{NO}_3^-$  sensor (Model SUNA V2, Satlantic, Halifax, NS, Canada), and a GPS device. The FLAMe platform measured water temperature ( $T$ ), dissolved oxygen (DO), pH, turbidity, specific conductivity, Chl  $a$ , and fluorescent dissolved organic matter (fDOM). Higher fDOM values are related to terrestrially derived organic matter [Spencer *et al.*, 2013] and are a proxy for dissolved organic carbon [Crawford *et al.*, 2015]. Spatial coordinates were recorded semicontinuously at 1 Hz, while measurements of  $\text{NO}_3^-$  were recorded at 0.1 Hz.

### 2.3. Data Processing

The raw  $\text{N}_2\text{O}$  concentration data ( $n = 101,862$ ) were processed using MATLAB (R2013b; Mathworks, Natick, MA, USA) software. To georeference the FLAMe and  $\text{N}_2\text{O}$  data, we determined the hydraulic and sensor response time lags using a series of step change experiments [Crawford *et al.*, 2015]. The hydraulic and sensor lag describes the time required for the instrument to detect a step change (42.3 s) caused by tube length, instrument responsivity, and equilibrator lag. The sensor responsivity of the  $\text{N}_2\text{O}$  analyzer was estimated using an equilibrator time constant  $\tau$  (61.6 s) that describes the time required for a 63% step change to occur. A wavelet denoising technique was applied to the  $\text{N}_2\text{O}$  concentration data to improve the signal-to-noise ratio of the signal [Fassbinder *et al.*, 2013]. For convenience of data processing and statistical analyses, all of the data streams were subjected to 30 s block averaging resulting in a data series of  $n = 3667$ .

The surface water  $\text{N}_2\text{O}$  concentration ( $[\text{N}_2\text{O}]$ ;  $\text{mol N}_2\text{O L}^{-1}$ ) was calculated from

$$[\text{N}_2\text{O}] = [\text{N}_2\text{O}_*] \times F(T, p) \quad (1)$$

where  $[\text{N}_2\text{O}_*]$  is the equilibrator concentration and  $F(T, p)$  is the solubility function at the given surface water temperature ( $T$ ) and pressure ( $p$ ) [Weiss and Price, 1980; Grefe and Kaiser, 2014]. The theoretical equilibrium  $\text{N}_2\text{O}$  concentration ( $[\text{N}_2\text{O}_{\text{amb}}]$ ,  $\text{mol N}_2\text{O L}^{-1}$ ) assuming water-atmosphere equilibrium was calculated similarly

$$[\text{N}_2\text{O}_{\text{amb}}] = [\text{N}_2\text{O}_{\text{amb}*}] \times F(T, p) \quad (2)$$

where  $[\text{N}_2\text{O}_{\text{amb}*}]$  is the ambient atmospheric concentration reading by the  $\text{N}_2\text{O}$  analyzer and  $F(T, p)$  is the solubility function. The ambient concentration was measured every 2 h. The analyzer was zeroed and spanned using analytical grade standards (Specialty Gases of America, Toledo, OH, USA) before each measurement campaign. The concentration precision after wavelet denoising is  $1.5 \text{ nmol mol}^{-1}$  [Fassbinder et al., 2013]. These two metrics,  $[\text{N}_2\text{O}]$  and  $[\text{N}_2\text{O}_{\text{amb}}]$ , are water temperature dependent. Therefore, we use their ratio to standardize the measurements with respect to the in situ water temperature as  $\text{N}_2\text{O}$  saturation ( $\text{N}_2\text{O}_{\text{sat}}$ )

$$\text{N}_2\text{O}_{\text{sat}} = \frac{[\text{N}_2\text{O}]}{[\text{N}_2\text{O}_{\text{amb}}]} \quad (3)$$

A novel aspect of the FLAME platform is its capacity to incorporate spatial coordinates to identify spatial patterns driving  $\text{N}_2\text{O}_{\text{sat}}$  across large spatial distances. A Getis-Ord  $G^*$  analysis of each data set identified clustering of statistically significant high and low  $\text{N}_2\text{O}_{\text{sat}}$  and  $\text{NO}_3^-$  values relative to neighboring points [Ord and Getis, 2010]. A 99% significance threshold was used to determine  $\text{N}_2\text{O}_{\text{sat}}$  and  $\text{NO}_3^-$  hot spots and cold spots (Arcmap v.10.3; ESRI, Redlands, CA, USA).

Using  $\text{CO}_2$  piston velocity ( $k$ ) measurements from the UMR [Crawford et al., 2016], we estimated the mean ( $n = 22$ )  $k$  using the temperature-adjusted  $\text{N}_2\text{O}$  Schmidt number [Wanninkhof, 1992]. Nitrous oxide fluxes ( $\text{nmol N}_2\text{O} - \text{N m}^{-2} \text{ s}^{-1}$ ) from the UMR were calculated as

$$\text{Flux}_{\text{N}_2\text{O}} = k \times ([\text{N}_2\text{O}] - [\text{N}_2\text{O}_{\text{amb}}]) \quad (4)$$

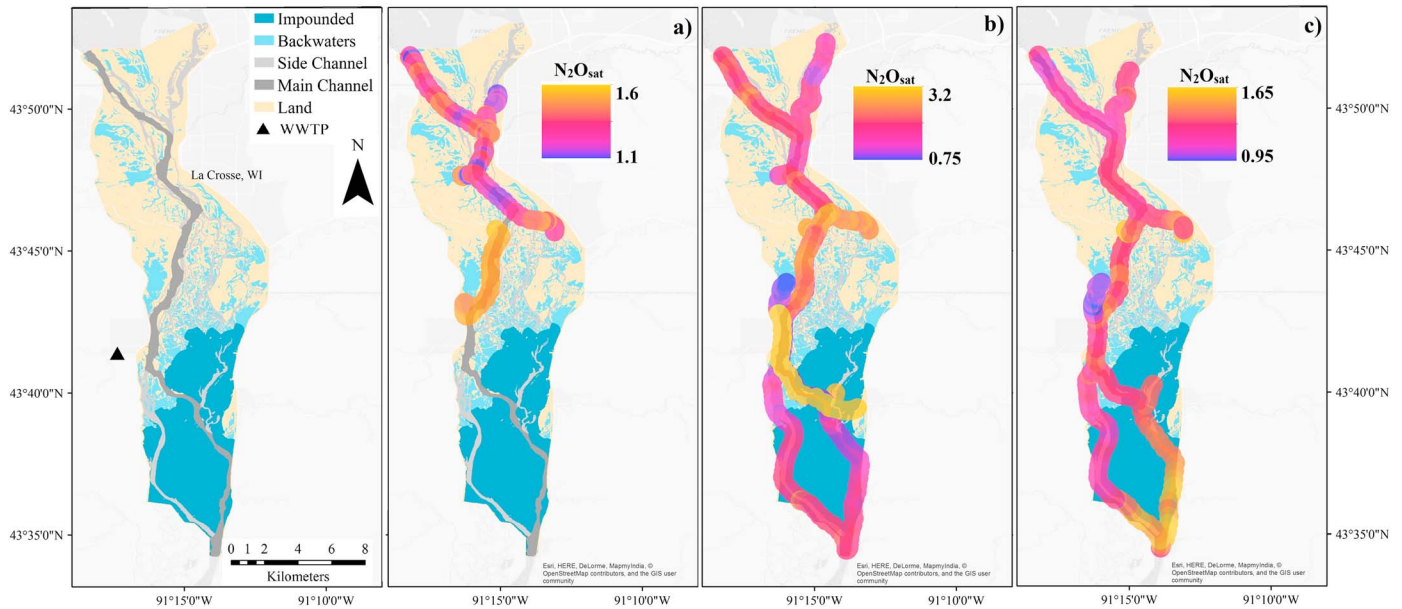

We assumed that variations in the evasion coefficient would be negligible within the UMR because of minimal channel geometry change [Wallin et al., 2011], and consequently,  $\text{N}_2\text{O}_{\text{sat}}$  and  $\text{Flux}_{\text{N}_2\text{O}}$  would be most sensitive to in situ production and consumption mechanisms [Beaulieu et al., 2015]. We estimated that  $\text{N}_2\text{O}_{\text{sat}}$  ratios greater than 1.2 and less than 0.8 were indicative of active production and consumption zones, respectively, while  $\text{N}_2\text{O}_{\text{sat}}$  values within this window were classified as zones of negligible production and consumption [Beaulieu et al., 2015].

#### 2.4. Ensemble Regression Trees

The controls on riverine  $\text{N}_2\text{O}_{\text{sat}}$  were identified independently for each river section using ensemble ( $n = 500$ ) binary bagged regression trees with the MATLAB *fitensemble* function (v.2015.b, Mathworks, Natick, MA, USA). This supervised learning method does not require an assumption of normality, and the bootstrap aggregation technique reduces prediction variance [De'ath and Fabricius, 2000; Sutton, 2005] making it a powerful tool for better understanding the controls on  $\text{N}_2\text{O}$  saturation [Baulch et al., 2011; Venkiteswaran et al., 2014; Lundy et al., 2015]. The relative predictor importance (RPI) of each explanatory variable on the corresponding  $\text{N}_2\text{O}_{\text{sat}}$  response was computed by summing the change in mean square error from splitting each predictor and dividing by the number of nodes. The importance was normalized with respect to the largest value [Lundy et al., 2015]; a response of 1 recognizes the independent variable with the greatest impact on the  $\text{N}_2\text{O}_{\text{sat}}$ , and a value of 0 indicates no influence. The variance of the ensemble regression model was determined by calculating the pseudo  $R^2$  value of model predicted and observed  $\text{N}_2\text{O}_{\text{sat}}$  ratios.

### 3. Results and Discussion

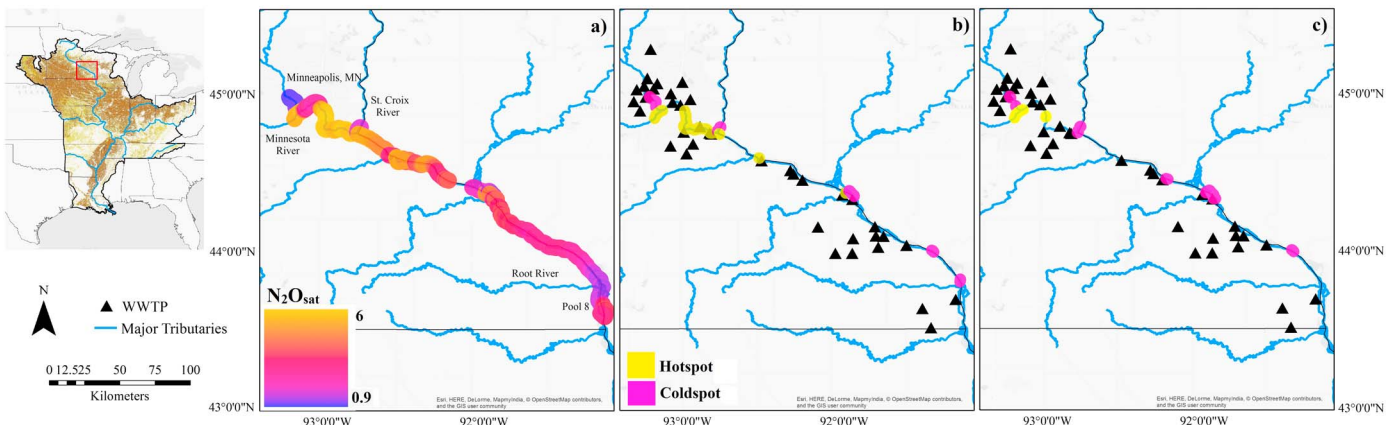

The UMR was supersaturated with  $\text{N}_2\text{O}$  throughout the ice-free measurement period, indicating it was an important atmospheric source (Figures 1 and 2a). Across all sampling locations and dates, the mean (standard deviation)  $\text{N}_2\text{O}_{\text{sat}}$  was 2 (0.9) times the atmospheric saturation (Table 1). The mean (standard deviation) fluxes at the regional scale (August) and throughout the ice-free period (April–October) were 0.5 (0.2) and

**Figure 1.** The temporal and spatial dynamics of  $N_2O_{sat}$  in Pool 8 of the UMR in (a) April ( $n = 298$ ), (b) August ( $n = 828$ ), and (c) October ( $n = 514$ ).

0.2 (0.1)  $nmol N_2O N m^{-2} s^{-1}$ , respectively, which are comparable to observations from nearby corn fields [Griffis *et al.*, 2013] and within the range observed in other large rivers [McMahon and Dennehy, 1999; Cole and Caraco, 2001; Hinshaw and Dahlgren, 2013]. Integrated over the measurement period (186 days), the UMR emitted 68 (20–115)  $mg N_2O - N m^{-2}$ . Because groundwater and most tributary flows are negligible in a river of this size, and because of the short residence time of upstream dissolved gases, our data indicate that the UMR actively produces  $N_2O$  throughout the year. Although, at certain times and places, external  $N_2O$  inputs could be significant, for instance, high discharge from the N-rich Minnesota River could affect  $N_2O_{sat}$  but these sources are poorly constrained.

During the June Pool 8 campaign, an instrument issue prevented  $N_2O_{sat}$  measurements greater than 4.8. Because we can only state that  $N_2O_{sat}$  was equal to or above 4.8, they were not included in the following analyses. However, the high  $N_2O_{sat}$  in Pool 8 in June is consistent with recent top-down measurements and modeling that found total emissions (direct + indirect) [Miller *et al.*, 2012; Griffis *et al.*, 2013] and indirect emissions from leaching and runoff [Chen *et al.*, under review] to be the highest during this period, likely because of the recent application of N fertilizers.

**Figure 2.** Inset: Agricultural land use within the UMR basin. Row crop (brown) and pasture (yellow) were drawn using information from the National Land Cover Database [Xian *et al.*, 2011]. (a) The regional-scale variability of  $N_2O_{sat}$  in the UMR ( $n = 1553$ ). Hot spots and cold spots of (b)  $N_2O_{sat}$  and (c)  $NO_3^-$  concentrations.

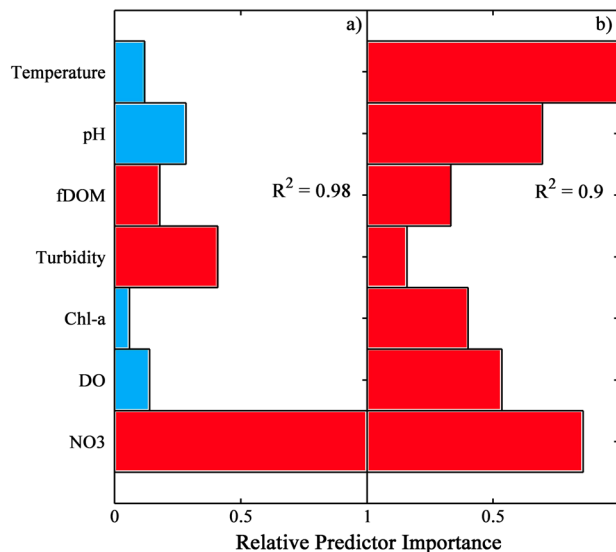

**Table 1.** The Mean (Standard Deviation) of  $N_2O_{sat}$ ,  $N_2O_{FLUX}$  ( $nmol N_2O N m^{-2} s^{-1}$ ),  $NO_3^-$  ( $mg NO_3^- L^{-1}$ ), DO (% Saturation), Chl *a* (Relative Fluorescence Units; RFU), Turbidity (Formain Nephelometric Units; FNU), fDOM (Quinine Sulfate Units; QSU), and Temperature ( $^{\circ}C$ ) During Each Sample Campaign

	Water Chemistry								
	$N_2O_{sat}$	$N_2O_{FLUX}$	$NO_3^-$	DO	Chl <i>a</i>	Turbidity	fDOM	pH	Temperature
Regional ( $n = 1553$ )	2.5 (0.9)	0.5 (0.2)	1.5 (1.3)	119.7 (16.4)	30.8 (12)	10.1 (6)	97 (13)	8.5 (0.2)	23.8 (0.6)
Pool 8—April ( $n = 298$ )	1.2 (0.1)	0.1 (0.06)	1.4 (1)	96.8 (3.2)	4.6 (2.1)	27.1 (35.8)	45.1 (11.3)	8.4 (0.2)	6.2 (0.7)
Pool 8—June ( $n = 474$ )	>4.8	>0.7	2 (1.5)	79 (9)	6.7 (2.5)	76.7 (81)	78 (27)	8 (0.5)	21 (0.4)
Pool 8—August ( $n = 828$ )	1.7 (0.3)	0.2 (0.1)	0.95 (1)	141.7 (32.6)	41.6 (20.3)	9.2 (4.8)	70.4 (21.7)	8.8 (0.3)	23.5 (0.9)
Pool 8—October ( $n = 514$ )	1.4 (0.2)	0.1 (0.06)	1.2 (0.6)	92.3 (5.6)	3.4 (1.3)	5 (1.6)	74.2 (17.3)	8.2 (0.1)	12 (0.7)

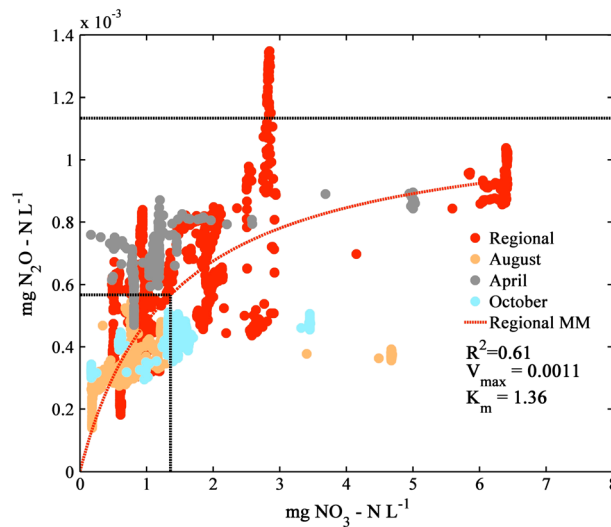

Spatial analyses, based on the Getis-Ord  $G^*$  statistic [Ord and Getis, 2010], identified four  $N_2O_{sat}$  hot spots along this section of the UMR (Figure 2b). Hot spots were generally within close proximity to municipal wastewater treatment plants (WWTP). These hot spots dissipated rapidly, presumably because of dilution and out-gassing over relatively short distances, suggesting that care should be taken when sampling nearby. The strength of these hot spots reflects differences in effluent discharge and river volume. Since  $NO_3^-$  hot spots were not observed downstream of each WWTP (Figure 2c), it is likely that  $N_2O$  was produced during wastewater processing prior to discharge into the UMR [Kampschreur et al., 2009]. However, WWTPs are relatively minor contributors to the total N in the UMR, with greater than 70% being from agricultural sources [Wall et al., 2013]. Our analyses identified five  $N_2O_{sat}$  cold spots (i.e., locations with anomalously low-dissolved  $N_2O$ ) along this reach that were collocated with  $NO_3^-$  cold spots (Figure 2c), indicating that  $NO_3^-$  concentrations are an underlying requirement for  $N_2O$  production.

Overall, the surface water  $NO_3^-$  (RPI = 1) concentration was the most important explanatory variable driving regional fluctuations in UMR  $N_2O_{sat}$  (Figure 3a), whereas throughout the ice-free period, temperature (RPI = 1) and  $NO_3^-$  (RPI = 0.86) were the most important predictors (Figure 3b). The strong relation with  $NO_3^-$  throughout the UMR was expected because it is linked to both nitrification and denitrification. These processes are well documented in rivers [Strauss et al., 2002; Beaulieu et al., 2011], lakes [Wang et al., 2009], reservoirs [Beaulieu et al., 2015], and estuaries [Owens, 1986; Murray et al., 2015]. In a well-oxygenated river

such as the UMR, the strong relation between  $NO_3^-$  and  $N_2O_{sat}$  suggests that nitrification is a likely pathway to  $N_2O$  production [Beaulieu et al., 2015]. This relationship also suggests that  $N_2O$  could be produced via denitrification, since the  $NO_3^-$  concentration in the surface water is likely an indirect measure of the  $NO_3^-$  available for diffusion into hypoxic sediments [Rosamond et al., 2012], i.e., the sediment denitrification potential. Other processes (e.g., dissimilatory nitrate reduction to ammonia (DNRA) and nitrifier denitrification) may produce  $N_2O$  simultaneously, but the fluxes associated with these production pathways are expected to be small and cannot be elucidated from our data or analyses. However, the kinetics of  $NO_3^-$  processing and concurrent  $N_2O$  production are affected by secondary environmental factors—including turbidity (RPI = 0.4), pH (RPI = 0.3), fDOM (RPI = 0.18), and DO (RPI = 0.14)—that may limit or enhance reaction rates (production via nitrification and consumption via denitrification).

**Figure 3.** Relative predictor importance (RPI) determined using ensemble ( $n = 500$ ) regression trees to predict  $N_2O_{sat}$  observations. Red and blue bars denote positive and negative relationships, respectively. The variable importance describes the explanatory power of a predictor on the  $N_2O_{sat}$  response. The pseudo  $R^2$  was determined from an observed  $N_2O_{sat}$  versus predicted  $N_2O_{sat}$  relation from the ensemble regression model. Each value was normalized to the most important predictor in each system, (a) the RPI of the regional-scale measurements and (b) the temporal (April, August, and October) RPI from Pool 8.

**Figure 4.** Measurements of N<sub>2</sub>O and NO<sub>3</sub> from the UMR basin. The red dashed line is the Michaelis-Menten (MM) function derived from the regional-scale campaign ( $n = 1553$ ). The black horizontal dashed line denotes the  $V_{max}$ , and the black dashed box represents the  $K_m$ .

[Beaulieu *et al.*, 2011] that underlies the horizontal asymptote observed for dissolved N<sub>2</sub>O concentrations in the UMR (Figure 4).

Using Michaelis-Menten kinetics [García-Ruiz *et al.*, 1998; Boyer *et al.*, 2006], we describe the weakening N<sub>2</sub>O response to N saturation as

$$[N_2O] = \frac{V_{max} \times [NO_3^-]}{K_m + [NO_3^-]} \quad (5)$$

with the parameters estimated using a nonlinear least squares fitting function (*enzkin*; v. R2013B; Mathworks, Natick, MA, USA). Here the [N<sub>2</sub>O] (mg N<sub>2</sub>O–NL<sup>–1</sup>) can be derived from the [NO<sub>3</sub><sup>–</sup>] (mg NO<sub>3</sub><sup>–</sup>L<sup>–1</sup>) with a  $V_{max}$  of 0.0011 (95% CI;  $\pm 4.1 \times 10^{-5}$ ) mg N<sub>2</sub>O–NL<sup>–1</sup> and a  $K_m$  of 1.36 ( $\pm 0.11$ ) mg NO<sub>3</sub><sup>–</sup>L<sup>–1</sup>. The  $V_{max}$  represents the system’s maximum [N<sub>2</sub>O] and the  $K_m$  is the [NO<sub>3</sub><sup>–</sup>] required to reach 50% of the  $V_{max}$ . The nonlinearity of Figure 4 implies that increasing NO<sub>3</sub><sup>–</sup> concentrations will have a progressively weaker effect on N<sub>2</sub>O concentrations in the UMR. In North America, river models project a doubling of the NO<sub>3</sub><sup>–</sup> exported to estuaries by the year 2050 [Seitzinger *et al.*, 2002]. Using the relation shown in Figure 4, a doubling of NO<sub>3</sub><sup>–</sup> would increase N<sub>2</sub>O emissions from the UMR by about 42% (95% CI; 32–52%). Conversely, the U.S. Environmental Protection Agency has established a goal to reduce N export by 45% by 2035. If these goals were achieved, N<sub>2</sub>O concentrations in the UMR would be decreased by about 32% (26–38%), implying a substantial reduction in N<sub>2</sub>O emissions. However, because our regression tree models indicated that N<sub>2</sub>O<sub>sat</sub> was influenced by secondary factors, these forecasts could be diminished, for instance, a reduction in turbidity (decreased substrate for nitrifying bacteria) would lower N<sub>2</sub>O<sub>sat</sub> and therefore these forecasts should represent an upper estimate.

While automated soil N<sub>2</sub>O measurement systems have become more common in recent years, techniques for continuous measurement of riverine N<sub>2</sub>O concentrations have lagged behind. The techniques applied in this study have potential to address this problem worldwide and could significantly reduce the uncertainty in riverine N<sub>2</sub>O emissions and the riverine emission factor (EF<sub>5r</sub>) provided by the Intergovernmental Panel on Climate Change (IPCC) [Nevison, 2000]. For instance, stationary in situ sampling platforms located at strategic locations within a stream network could be used for emission upscaling [Turner *et al.*, 2015] to develop regionally appropriate, Tier II EF<sub>5r</sub> values. Further, such data could be used to improve our understanding of the interannual variability and long-term dynamics of dissolved riverine N<sub>2</sub>O and emissions.

We posit that these secondary factors indirectly dampen the N<sub>2</sub>O<sub>sat</sub> response by reducing the efficiency of NO<sub>3</sub><sup>–</sup> removal (i.e., N<sub>2</sub>O production potential) at high solute concentrations [Mulholland *et al.*, 2008]. This response has been attributed to limits on denitrification—including dissolved oxygen and carbon [Mulholland *et al.*, 2008]—that were also identified by our ensemble regression tree model. These data also classified pH as an important predictor, likely because it affects the rates of denitrification [Knowles, 1982] and nitrification [Strauss *et al.*, 2004]. We hypothesize that the positive relation identified between turbidity and N<sub>2</sub>O<sub>sat</sub> in the model reflects the fact that nitrifying bacteria bind to suspended particles in the water column [Beaulieu *et al.*, 2010]. Together, these factors affect the fraction of NO<sub>3</sub><sup>–</sup> converted to N<sub>2</sub>O at N saturation

#### 4. Conclusions

Our data and analyses demonstrate that the UMR is supersaturated with N<sub>2</sub>O during the ice-free period and is an important source of atmospheric N<sub>2</sub>O. The regression tree models evaluated in this study indicate that NO<sub>3</sub><sup>-</sup> is the dominant control on N<sub>2</sub>O concentrations but that other environmental variables may limit NO<sub>3</sub><sup>-</sup> processing. Given the significant nonlinear relation between NO<sub>3</sub><sup>-</sup> and N<sub>2</sub>O in the UMR, we expect that a doubling of N loading is likely to cause a substantial (32–52%) rise in dissolved N<sub>2</sub>O concentrations and atmospheric emissions.

#### Acknowledgments

We thank William Breiter, Michael Dolan, Mark Dornblaser, Stephen Powers, and Matt Erickson for field and laboratory assistance. This work was supported by the U.S. Department of Agriculture, grant USDA-NIFA 2013-67019-21364, USDA-ARS, and the U.S. Geological Survey's LandCarbon program.
